ABSTRACT

Researchers from Inorganic Chemistry Department at the University of Alicante have developed a new procedure to obtain heterogeneous monolithic catalysts with polymeric support that allow to accelerate catalytic reactions in an optimal way at moderate temperatures, being especially suitable in Preferential Oxidation of Carbon in Hydrogen Rich Gases (CO-PROX). These novel catalysts have been manufactured by 3D printing with complex geometries, improving the performance of current supports. These heterogeneous catalysts are characterized because they have similar conversion and selectivity profiles to current unsupported powder catalysts. They have increased catalytic activity during prolonged reaction times and greater resistance to friction wear. We are looking for companies interested in acquiring this technology for commercial exploitation.

INTRODUCTION

Catalysts used in heterogeneous catalysis consist of an inert support on which a phase with catalytic activity (active phase) is deposited.

The most relevant supports are monoliths with cellular structure (honeycomb). It is a set of parallel channels of millimeter size through which the fluid circulates, and in the walls of these channels that the active phases are supported. These monoliths are characterized because they are easily manipulated to install or replace them, they do not generate preferential paths in the fluid, they are robust, they present a great resistance to friction wear, they have low pressure drops and great characteristics of heat and mass transference.

The monolithic supports are used in a wide range of applications, among them the Preferential Oxidation of Carbon Monoxide (CO) in Hydrogen (H₂) Rich Gases (CO-PROX). The CO-PROX is necessary for proper development of PEMFC Polymer-Electrolyte Membrane Fuel Cell.

In the CO-PROX reaction, the cell-structured monolithic support provides the best use of the active phase, as it allows more catalyst to be charged, as well as operating under more adiabatic conditions.

The use of honeycomb monoliths in heterogeneous catalysis is limited both by the technology available for their manufacture (they are manufactured by extrusion) and by the techniques available to support the active phases (they are subsequently incorporated after immersion in a dip-coating suspension, and the homogeneity of the coating is in doubt).

The monoliths used commercially are manufactured from refractory ceramic materials with high thermal and mechanical stability (e.g. cordierite, silicon carbide, etc.).

The use of polymeric materials to manufacture catalyst supports is simple and economic; however, currently it is not carried out due to the low thermal stability of polymers compared to ceramics, as well as the difficulty of supporting active phases in polymeric substrates.

Thermal stability is not an obstacle in low-temperature catalytic applications such as CO-PROX reaction. However, the adequate anchoring of the active phase on the polymeric support is an unresolved scientific-technical challenge.

Therefore, it is necessary to develop new heterogeneous catalysts able of being used in Preferential Oxidation of Carbon Monoxide (CO) in Hydrogen (H₂) Rich Gases (CO-PROX).

TECHNICAL DESCRIPTION

In order to overcome limitations described above, a **new heterogeneous catalyst** have been developed comprising a polymeric support formed by a set of channels on, at least, one active phase (which is responsible for carrying out the catalytic reaction) is deposited homogeneously.

This polymeric support is preferably monolithic (*see Figure 1*) with any geometry (cube, sheet, disc, cylinder, etc.), and its main function is to disperse, stabilise and provide great mechanical properties to the active phase. In addition, it has a cellular structure and it is formed by a plurality of channels and surfaces that they may be smooth or have irregularities in their walls (for example: slits with different geometries, perforations, roughness, etc.).

Figure 1: channel scheme of a monolith designed with prismatic slits along the channel walls.

These irregularities are full of active phase and they facilitate the **homogeneous distribution** along the channel walls of the monolith (*see Figure 2*), thus increasing its useful working surface. In addition, it prevents channels with an excess of active phase (that it could block channels and prevent proper circulation of the reagent), as well as channels with active phase defect (that it would be inefficient in accelerating the catalytic reaction). In this sense, both the excess and the defect of the active phase in the walls of the channels are a detriment to the overall efficiency of the monolithic catalyst.

Figure 2: photograph taken by SEM microscopy showing the homogeneous distribution of the powder catalyst on the channel walls of a polymeric monolith.

On one hand, the **monolithic support** is a **polymeric resin that is photosensitive to ultraviolet light and stable up to 300°C**, i.e. it is very suitable for catalytic reactions at moderate temperatures, such as Preferential Oxidation of Carbon Monoxide (CO) in Hydrogen (H₂) Rich Gases whose useful operating range does not exceed this thermal stability limit.

On the other hand, the **active phase** is responsible for the catalytic activity and it allows to carry out the reaction of interest. There are different types of active phases, e.g. metals, metal oxides or combinations thereof. In this case, **copper oxide (CuO) supported on cerium oxide (CeO₂)** has been used as active phase. The percentage by weight of the active phase in the catalyst is less than 6% (*see Figure 3*).

Figure 3: chemical analysis using EDS technique showing the distribution of the chemical elements of the CuO/CeO₂ catalyst deposited in the channels of the monolithic support, being (a) Cu and (b) Ce.

Optionally, in order to **improve thermal stability and increase the amount of active phase** incorporated in the resin, different charges (e.g. carbon and/or silica) can be added in quantities less than 3.5% by weight of the total weight of the polymeric support.

The procedure to obtain this novel heterogeneous catalyst comprises the following **steps**:

1. To get **monolithic form** to the thermostable polymeric resin catalytic support through **3D printing**, and later it is cured by exposure to ultraviolet light. Optionally, carbon and/or silica charges can be added to the liquid resin by magnetic agitation.
2. **Immersion coating** on, at least, one surface of the substrate obtained at the previous point with a suspension comprising the active phase(s). The solvent for preparing this suspension can be water, alcohol or a combination of these, and the solvent for the CuO/CeO₂ active phase can be water. Optionally, each channel can be coated with this suspension. This stage can be carried out more than once.
3. Rotate the product horizontally and **dry it under dynamic conditions** (rotation) to ensure that the active phase continues distributed evenly.
4. **Heat treat** in an **inert atmosphere** (e.g. nitrogen, argon or helium) to remove volatile substances from the substrate and strengthen the bond between the active phase and the substrate. Optionally, in order to eliminate the excess of active phase that could obstruct the channels of the support, a stream of compressed air can be used.
5. **Heat treat** in an **oxidising atmosphere** (e.g. air, oxygen or a mixture of oxygen and nitrogen) to improve the accessibility of the reagents to the active phases present on the channels.

TECHNOLOGY ADVANTAGES AND INNOVATIVE ASPECTS

The main advantages of this novel polymeric catalyst are listed below:

- 1) The presence of slits with prismatic geometry in the channels of the polymeric monolith facilitates the homogeneous distribution of the active phase.
- 2) The homogeneity of the coating inside the channels prevents excess active phase in some and deficit in others, thus ensuring catalytic efficiency of the catalyst.
- 3) It presents conversion and selectivity profiles similar to the current powder catalysts without supporting.
- 4) It has been shown to have great catalytic activity for prolonged reaction times and, therefore, it is more robust than powder catalysts.
- 5) It is more resistant to friction wear than current catalysts.
- 6) It has low pressure drops.
- 7) It has really great heat and mass transfer characteristics.

INNOVATIVE ASPECTS OF THE TECHNOLOGY

In recent years, packaged bed reactors and pellets used in the area of heterogeneous catalysis have been progressively replaced by cellular geometry monoliths. These monoliths exhibit great heat and mass transfer characteristics, low pressure drops, they are easily manipulated for installation and replacement, and they do not generate preferred paths in the fluid.

Commonly, monoliths are manufactured by extrusion, which it limits their geometry to straight and parallel channels. However, using 3D printing it is possible to design and manufacture monolithic supports with complex geometries that allow to improve the performance of the current supports at present.

Polymeric resin monoliths have been designed and manufactured by 3D printing for using as catalyst supports (see Figure 4), obtaining very satisfactory results and being pioneers in the use of polymers as monolithic supports in heterogeneous catalysis.

Figure 4: example of monoliths manufactured by 3D printing and detail of two channels obtained by SEM microscopy (right).

The current procedures to incorporate active phases in monoliths manufactured in non-polymeric materials (for example, cordierite or silicon carbide), are not applicable to polymeric resins due to the bad adherence of the catalyst to the support. However, following the procedure described in the present invention, a homogeneous coating of the monolith channels is obtained with an adequate distribution of the active phases.

In this procedure, it is not necessary to carry out previous attacks on the resin, and a single impregnation step is sufficient to cover homogeneously the surface of the monolith channels.

Another key aspect of this novel procedure is to carry out a heat treatment in an inert atmosphere after impregnation, as well as an additional heat treatment in an oxidising atmosphere. In this way, a strong anchorage of the powder catalyst to the channels of the monolith is achieved.

In addition, after several experimental studies, it can be concluded that modifying the composition of the resin by adding carbon and/or silica charges, modifying the design of the channels from smooth to slits, and increasing the number of impregnation stages, it increases the percentage by weight of the active phase in the catalyst.

CURRENT STATE OF DEVELOPMENT

Catalytic activity tests have been **successfully performed at laboratory level** (TRL 4/5) for the reaction of Preferential Oxidation of Carbon Monoxide (CO) in Hydrogen (H₂) Rich Gases (CO-PROX).

It can be concluded that the **general behaviour** of these novel catalysts is **similar to the unsupported commercial powder catalysts**, presenting qualitatively very similar conversion and selectivity profiles.

Furthermore, after 10 hours of reaction, both the conversion (95%) and the selectivity (90%) remain stable, thus demonstrating their **great catalytic activity** for prolonged reaction times (see *Figure 5*).

Figure 5: profiles of CO conversion and CO selectivity towards the product CO₂ and temperature, in a stability test of 10 hours duration.

MARKET APPLICATIONS

The present invention is framed in the field of **heterogeneous catalysis**, that is, in those reactions that take place when the catalyst is in a phase (solid, liquid or gas) different from the reagents.

This novel polymeric catalyst can be used in those **catalytic applications** that occur at a temperature lower than the degradation of the polymer, i.e. **below 300°C**, for example, in Preferential Oxidation of Carbon Monoxide (CO) in Hydrogen (H₂) Rich Gases (CO-PROX).

Henceforth, this technology finds its application in the following industrial sectors:

- Chemical sector.
- Energy Sector.

COLLABORATION SOUGHT

We are looking for companies interested in acquiring this technology for commercial exploitation through:

- Patent licensing agreements.
- Development of new applications.

INTELLECTUAL PROPERTY RIGHTS

This invention is protected under **patent application**:

- Title of the patent: "Catalizador heterogéneo con soporte polimérico".
- Application number: P201930487.
- Application date: 31st May, 2019.

MARKET APPLICATION (4)

Pollution and Environmental Impact
Materials and Nanotechnology
Chemical Technology
Transport and Automotive
